Abstract

Many influential models of sentence production (e.g., Bock & Levelt, 1994; Kempen & Hoenkamp, 1987; Levelt, 1989) emphasize the central role of verbs in structural encoding, and thus predict that verbs should be selected early in sentence formulation, possibly even before the phonological encoding of the first constituent (Ferreira, 2000). However, the most direct experimental test of this hypothesis (Schriefers, Teruel & Meinhausen, 1998) found no evidence for advance verb selection in verb-final (SV and SOV) utterances in German. The current study, based on a multi-word picture-word interference task (Meyer, 1996; Schriefers et al., 1998) demonstrates that in Japanese, a strongly verb-final language, verbs are indeed planned in advance, but selectively before object noun articulation and not before subject noun articulation. This contrasting pattern of advance verb selection may reconcile the motivation for advance verb selection in structural encoding while explaining the previous failures to demonstrate it. Potential mechanisms that might underlie this contrasting pattern of advance verb selection are discussed.

Keywords: sentence production; advance planning; picture-word interference; Japanese
**Introduction**

Uttering a sentence requires that a single message be converted into a sequence of words. There is widespread agreement that this conversion occurs incrementally, meaning that speaking can begin before the entire utterance is planned. A strong version of the incrementality hypothesis (e.g., Brown-Schmidt & Konopka, 2008; Brown-Schmidt & Tanenhaus, 2006; Griffin, 2001; Iwasaki, 2011; Schriefers, Teruel & Meinshausen, 1998) posits that the sentence plan is, most of the time, developed in the same order that the words are uttered, i.e., the first word is planned first, the second word second, and so on. This strong version of the incrementality hypothesis holds that the sentence plan is developed on a *just in time* basis, such that words are planned right before they are uttered. This approach might be beneficial for reducing memory demands and avoiding interference between multiple activated lexical items, but it requires that utterance plans be flexibly adjusted to the word order demands of a language, so as to avoid ‘look-ahead’ in planning. The best tests of this strong incrementality arise in situations where words that play a central role in the organization of a sentence are forced to appear late in the utterance, due to the word order constraints of a language. Here we examine such a case, focusing on evidence for look-ahead effects in Japanese, a language whose word-order constraints force verbs to appear in utterance-final position.

**The timing of verb selection in sentence production**

Linguistic and psycholinguistic evidence suggests that verbs are critical for structural processing. This points to the early encoding of verbs in utterance formulation. Accordingly, many influential models of sentence production (e.g., Bock & Levelt, 1994; Ferreira, 2000; Kempen & Hoenkamp, 1987; Levelt, 1989) adopt the view that the verb’s syntactic representation (i.e., *lemma*; Kempen & Huijbers, 1983) guides structural processes, and thus they
predict that a verb’s lemma is selected before the relevant structural processes are performed. Most explicitly, Ferreira (2000) argued that selection of a verb’s lemma (or the head of any phrase) must be performed before phonological encoding of the first phrase of a sentence is finalized.

Despite the emphasis on verbs’ early encoding in models of sentence production, the experimental evidence from tests of this issue is equivocal at best. Some suggestive evidence for advance verb selection comes from Kempen & Huijbers (1983), who found that changing the target verbs between experimental blocks delayed speech onset for both verb-subject and subject-verb sentences in Dutch, though with a greater delay for verb-subject than subject-verb sentences. This suggests that either verbs’ conceptual representation, their lexical representation, or both are at least partially planned in advance, although the results are ambiguous between these three interpretations. In addition, Schnur, Costa and Caramazza (2006) and Schnur (2011), using the multi-word picture-word interference task (Meyer, 1996), found that distractors that are phonologically related to the target verb in SV and SVO utterances facilitated speech onset, suggesting that even the phonological representation of a verb is encoded in advance. However, this evidence is hard to interpret because facilitative effects may alter normal planning in favor of advance planning of verbs, due to potential feedback activation from the phonological level to higher levels, and because these findings conflict with existing evidence that suggests a narrow scope of planning at the phonological level (e.g., Griffin 2001; Meyer, 1996; Meyer, Slederink & Levelt, 1998; Wheeldon & Lahiri, 1997). Nevertheless, the studies by Schnur and colleagues are broadly consistent with models that posit advance selection of verbs.

On the other hand, the most direct experimental test of the issue failed to provide evidence for advance verb selection. Schriefers and colleagues (1998) used an extended version
of the picture-word interference paradigm in German. In five experiments, participants were presented with action pictures with distractor words. Participants’ task was to complete a lead-in fragment by describing a picture as quickly as possible using either a verb-initial (e.g., laugh – the girl) or verb-final (e.g., the girl - laugh) clause, while ignoring distractors (e.g., cry).

Schriefers and colleagues reasoned that if verb selection occurs prior to utterance onset then the Semantic Interference (SI) effect, a relative delay of utterance onset due to semantic relatedness between target and distractor verbs, should obtain even in verb-final utterances. However, distractors that were semantically related to the target verbs elicited SI effects only in verb-initial utterances (although see Hwang & Kaiser, 2014 for evidence from English to the contrary).

These findings led some researchers to conclude that verb selection is not necessarily performed in advance (Allum & Wheeldon, 2007; Iwasaki, 2011). This paper attempts to reconcile the theoretical motivation for advance verb selection and the previous empirical failure to

---

1 Hwang and Kaiser (2014) showed a semantic interference effect from the verb in English SVO sentences, suggesting that advance verb selection occurs before subject articulation. This pattern contrasts with the results from Schriefers et al. (1998). However, Hwang and Kaiser’s choice of unrelated distractors was problematic in multiple respects, making it hard to interpret the results. First, the related and unrelated distractors were not matched in terms of number of repetitions throughout the experiment. Each of the related distractors was presented twice, while the unrelated distractors were presented only once, leading to a potential independent advantage for related distractors. Second, the related and unrelated distractors were not matched in terms of lexical frequency. The mean corpus log frequency of the related distractors were 7.74 (SEM = 0.19) while that of the unrelated distractors were 7.11 (SEM = 0.24) and this difference was marginally significant in two tailed t-test that does not assume equal variance, even though the number of items was very small (4 for the related condition and 8 for the unrelated condition). Finally, Hwang and Kaiser used adjectives as unrelated distractors. They argued that same category distractors (i.e., verb distractors) might cause interference and thus they should be avoided, but this is exactly the reason why the same grammatical category distractors should be used for related and unrelated condition alike. Otherwise, the interference effect cannot be reliably identified as a semantic interference effect. It cannot be identified as grammatical category mismatch effect either, because there is no guarantee that verb distractors and adjective distractors have the same effect on production of the sentence-initial noun, since adjectives and verbs have very different distributional relations to nouns. Therefore, we consider it premature to take the verb interference effect in Hwang & Kaiser’s English experiment as evidence for advance verb planning before subject nouns in English. Indeed, we failed to replicate Hwang & Kaiser’s semantic interference effect using balanced related vs. unrelated verb distractor in an English SVO sentence production task, with a more powerful design (# of participants = 36; # of items = 24), even though the distractors were shown to be effective in a single verb naming context (Momma, Slevc & Phillips, 2015).
demonstrate it by examining the timing of verbs’ lemma selection at two different points in sentences: before object and before subject noun articulation.

Linguistic Contrasts between Subjects and Objects

Linguistic analyses suggest that objects are more strongly dependent on verbs than subjects in many respects. First, it has sometimes been argued that a verb and its internal arguments constitute the verb’s argument structure while external arguments are not part of such a structure (cf. Marantz, 1984; Kratzer, 1996; 2002). This claim is derived from the observation that the choice of the object, but not the subject, has a significant impact on the meaning of the verb. Second, verbs do not select subjects in the same sense that they select objects – a subject is obligatorily present regardless of the properties of the verb (Chomsky, 1981; see Lasnik, 2003, for a discussion), while the presence/absence of an object depends on the subcategorization property of the verb (e.g., Haegeman, 1991). Third, subjects and objects are considered to receive case from different sources. The case-assigner of object nouns is generally considered to be the lexical head V(erb), while that of subject nouns is considered to be the functional head I(nflection) in nominative-accusative languages (Chomsky, 1981). Finally, objects have a closer constituency relationship with the verb. In a transitive sentence, the verb and the object noun phrase together form a verb phrase, while a subject noun phrase and a verb do not by themselves form a syntactic constituent under most accounts (e.g., GB, Chomsky, 1981; HPSG, Pollard & Sag, 1994; LFG, Bresnan, 2001). These linguistic analyses all suggest that object nouns are more closely associated with verbs than subject nouns, both syntactically and semantically.

The Current Study

Given the difference between subject and object nouns in terms of their dependency on verbs, it is possible that verb selection might be required before object articulation, but not
before subject articulation. To test this hypothesis we adapted the extended picture-word interference paradigm (Meyer, 1996; Schriefers et al., 1998) to Japanese, with some modifications. We exploited two properties of Japanese: strict head-finality and liberal argument dropping. Specifically, in order to probe the timing of verb selection both before subject and object articulation based on speech onset latency, one needs to be able to naturally elicit two types of sentences: one starting with an object noun phrase, another starting with a subject noun phrase, preferably in canonical word order. This condition can naturally be met with Japanese. Japanese allows complete sentences consisting either of subject-verb (SV) or object-verb (OV) sequences. The OV structure allows us to test whether verbs are selected prior to object noun phrase articulation. SV and OV utterances are both naturally producible grammatical sentences in Japanese, and they can be closely matched in terms of the length of their initial noun phrase. Therefore, they are well suited for comparing the status of advance verb planning before subjects and objects are uttered.

The three experiments reported here used a similar picture-word interference design and are closely related to each other. Experiment 3 was a phrase-production task that tested the key question of the current study: whether verbs are planned before object articulation but not before subject articulation. Experiment 1 was a single-word production task eliciting only verbs, to verify the effectiveness of the picture-distractor pairs used in Experiment 3. Example stimuli used in Experiments 1 and 3 are illustrated in Figures 1 and 2 below. Experiment 2 was also a single-word production task eliciting only nouns, to verify that any interference effects observed in Experiment 3 were reflections of verb planning rather than noun planning. These three experiments in concert are necessary to attribute the presence/absence of a verb-based semantic interference effect to the presence/absence of advance selection of verb lemmas.
Experiment 1

Participants

Twenty-four students from Hiroshima University in Japan participated in all three experiments in exchange for 500 yen.

Materials

Twenty-four action pictures were chosen from the UCSD International Picture Naming Database (Szekely et al., 2004): half corresponding to transitive verbs, and the other half corresponding to intransitive verbs. For each picture two types of distractors were chosen, one semantically related to the target verb and the other unrelated to the target verb. The related distractors were chosen based on two native Japanese speakers’ intuitive judgments, and they involved synonym, antonym, or co-hyponym relations. Importantly, the related distractor words were all used as unrelated distractors for other pictures, with the effect that the set of distractor words was identical in the related and unrelated conditions. The unrelated distractors were also matched to the target word in terms of transitivity. This ensured that uncontrolled parameters of the distractor words such as frequency, length and orthographic complexity could not differentially affect speech onset latencies in the related and unrelated conditions. Neither the related or unrelated distractors had a systematic phonological relationship to the target words.

Procedure

Participants were tested in a sound-attenuated, dimly lit room with an experimenter present. In a familiarization phase they first saw each picture and produced the associated target verb, and then practiced the action-naming task using pictures and distractors that were not
included in the experimental set. In the experimental session for Experiment 1, participants were instructed to produce one word that describes the action depicted by each picture as soon and as accurately as possible. On each trial a fixation-cross appeared at the center of the screen for 500 ms with a brief click sound (used for calculating speech onset), and then an action picture appeared simultaneously with a written distractor word. The distractor word disappeared after 300 ms, while the picture remained for 1500 ms. A 3000 ms blank screen separated the trials. Participants saw each picture twice, in the related and unrelated conditions, in different blocks. The ordering of pictures within a block was randomized for each participant, and the presentation of a picture with the related distractor in the first vs. second block was counterbalanced across participants.

**Analysis**

For each trial, speech onset latency was manually measured, specifically, the interval between the click sound and the onset of speech minus 500 ms, using Praat (Boersma & Weenink, 2012). The measurer was blind to the conditions, although he could identify the target utterances. Any trials with disfluencies, audible non-speech noise before utterance onset, or speech onset of more than 2000 ms were excluded. In addition, for each participant, trials with response times more than two standard deviations away from that individual’s mean RT were excluded. In total, 12.7% of the data points were excluded (7.3% due to errors and 5.4% due to trimming²). Both mean and dispersion (standard deviation) of each condition was analyzed. The analysis of dispersion was conducted here because (1) the mean analysis of Experiment 3 reported below does not yield unequivocal results and this analysis can serve as a point of comparison for the same analysis that was conducted for Experiment 3 and (2) there are good reasons to think that the semantic interference effect, or incongruity effects in any Stroop-like

² Analysis without trimming yielded the same results.
task, might not be best captured by a difference in the sample mean (Heathcote, Popiel & Mewhort, 1991; Scaltritti, Navarrete & Peressotti, 2014).

Results

Mean RTs (of participant averages) in milliseconds as a function of Verb type and Relatedness in Experiment 1 is shown in Table 1.

A mixed effects model with maximal random effects structure was constructed, followed by model simplification based on a maximum likelihood ratio test, with the alpha level of 0.1. As a result, the random slope of any factor by items or by subjects was not significant (all $p$s > 0.15). Thus, we report models with by-subjects and by-items intercepts; This analysis revealed an effect of relatedness ($\beta = 31.03$, $SE = 10.93$, $|t| = 2.84$, $p < 0.01$). In both models, neither the effect of transitivity nor the interaction between relatedness and transitivity was significant (all $p$s > 0.85).

In order to make a comparison between this experiment and Experiment 3, we conducted planned comparisons with Bonferroni correction between related conditions and unrelated conditions for transitive and intransitive verbs. Both transitive ($\beta = 33.55$, $SE = 10.96$, $z = 3.06$, adjusted $p < 0.01$) and intransitive verbs ($\beta = 28.26$, $SE = 10.77$, $z = 2.62$, adjusted $p < 0.01$) independently showed a reliable semantic interference effect.

---

3 We have not conducted a full ex-Gaussian distributional analysis because we did not have enough trials per condition to obtain a stable estimate of the ex-Gaussian parameters. Standard deviation can capture a simple measure of the distributional parameter that is not at all ($\sigma$) or not strongly ($\tau$) reflected by sample mean.

4 Barr et al. (2013) argued against this data-driven approach for selecting random effect structures in confirmatory hypothesis testing. For this experiment, including the maximal random effects structure following Barr et al. (2013) did not change the statistical pattern (but see Experiment 3 for diverging results and discussion).
A repeated measures ANOVA analysis in which each cell represented a participant’s (for F1) or an item’s (for F2) standard deviation (see Heathcote et al., 1991 for an analogous method of analysis in the Stroop task) revealed that the standard deviations in the related and unrelated conditions were significantly different (F1(23) = 21.36, p < 0.01; F2(23) = 7.71, p = 0.01), without any interaction with verb type (p > 0.5). This suggests that the semantic relatedness of the distractor has an effect on the dispersion of the reaction time distribution. This semantic interference effect on dispersion is visualized in Figures 3-4 by means of vincentile plots (e.g., Vincent, 1912; Staub, 2010), using only five bins due to the relatively small number of trials per condition per participant. These plots suggest that the semantic interference effect is only reliably identified in the right tail of the distribution (i.e., for slow responses), which is normally reflected by the τ parameter of an ex-Gaussian distribution, and has the following relation to the sample standard deviation: \( S = \sqrt{\sigma^2 + \tau^2} \). We however cannot identify whether the significant effect of relatedness resides in \( \sigma \) or \( \tau \) from the current experiment, and it is possible that the semantic interference effect might reside in both parameters.

FIGURE 3 HERE

FIGURE 4 HERE

Discussion

The aim of Experiment 1 was to test whether the set of verb distractors would reliably elicit a semantic interference (SI) effect. The results clearly show that the verb distractors were indeed effective in eliciting an SI effect regardless of transitivity, both in mean and standard deviation measures (for a discussion of how these measures relate to the ex-Gaussian parameters, see Heathcote et al., 1991). Hence, the same verb-distractor pairs were suitable for testing sentence production in Experiment 3.
Experiment 2

Participants

The same set of participants as in Experiment 1 participated in Experiment 2, except that one participant was excluded due to recording failure. The order of Experiments 1 and 2 was counterbalanced across participants.

Materials

24 new pictures from the IPNP were chosen to elicit the bare target nouns that were used also in Experiment 3, i.e., without associated actions. No actions were depicted in the pictures, unlike in Experiment 1. The distractor words, as well as the pairing between target nouns and distractor words, were kept constant as in Experiments 1 and 3.

Procedure & Analysis

The procedure was identical to Experiment 1, except that participants were instructed to describe the object depicted in the pictures in one word i.e., a noun. The analysis procedures were identical to Experiment 1.

Results

Speech onset latency did not significantly differ across conditions. No effect of noun type, relatedness, or interaction was found ($ps > 0.35$). Mean RTs (of participant averages) in milliseconds as a function of Noun type and Relatedness in Experiment 2 are shown in Table 2 below. A standard deviation analysis as in Experiment 1 revealed no effect of Noun type, Relatedness, or interaction between them (all $ps > 0.15$).

TABLE 2 HERE

Discussion
The results of Experiment 2 suggest that there was no systematic relationship between the target nouns and distractor verbs that affected utterance onset latency. This is important for ensuring that the nouns that were used in Experiment 3 have no accidental relationship to the distractor verb in a way that could have altered the pattern of semantic interference effects.

**Experiment 3**

**Participants**

The same set of participants participated in Experiment 3 after completing Experiments 1 and 2, following a short break.

**Materials**

The same set of picture-distractor pairs was used with identical presentation parameters as in experiment 1. The target nouns preceding the target verbs were matched in mean length (number of moras: 2.33 for the transitive condition and 2.5 for the intransitive condition). The transitive condition targeted 11 inanimate and 1 animate nouns, and the intransitive condition targeted 8 inanimate and 4 animate nouns. As participants saw the same set of pictures and distractors in Experiment 1, they had seen each picture four times by the end of Experiment 3\(^5\).

**Procedure & Analysis**

The same procedure was followed as in Experiment 1 and 2, except that participants were instructed to describe the action depicted in the pictures in sentential forms using two words, i.e., a noun, inflected with a case particle, followed by a verb. This elicited an SV sentence for the intransitive action pictures, and an OV sentence for the transitive action pictures. The same analysis procedure was adopted as in Experiment 1 and 2. In total, 13.3% of the trials were excluded (9.4 % due to errors, and 4.9% due to trimming).

---

\(^5\) This number of repetitions is lower than in many other PWI studies, which often involve 10 or more repetitions per picture. (e.g., Schriefers et al., 1990; 1998)
Results

Mean RTs (of participant averages) in milliseconds as a function of Sentence type and Relatedness in Experiment 3 is shown in Table 3 below.

TABLE 3 HERE

The same mixed effects model analysis procedure was applied as in Experiment 1. After model simplification based on maximum likelihood ratio tests, the model with both by-subjects and by-items intercepts revealed a marginally significant interaction (β = 25.20, SE = 13.08, |t| = 1.93, p = 0.054)⁶. There were no main effects of relatedness or sentence type (ps > 0.7).

As in Experiment 1 we conducted planned comparisons with Bonferroni correction between related and unrelated conditions for OV and SV sentences. These analyses showed that verb-related distractors significantly delayed sentence onsets in OV sentences (β = 26.53, SE = 9.11, z = 2.91, adj. p < 0.01), but not in the SV condition (p > 0.95).

Also, a post-hoc comparison of noun frequencies between OV and SV conditions was conducted to ensure that the differential effect of relatedness on OV and SV conditions was not attributable to the properties of the nouns. Based on the Tsukuba Web Corpus (http://corpus.tsukuba.ac.jp/), the mean log frequencies of the nouns did not differ between the transitive (M = 10.80; SEM = 0.39) and intransitive (M = 9.63; SEM = 0.58) conditions, although there was a trend toward a difference in a two-tailed t-test (p = 0.11). A further test using individual items found no correlation between noun frequency and the amplitude of the effect of semantic relatedness (r = 0.07, p > 0.7).

As in the verb-only experiment (Experiment 1), we also analyzed the difference in the standard deviation of the Related vs. Unrelated conditions. This analysis can be thought of as a

⁶ A model with maximal random effect structure (Barr, 2013) yielded non-significant interaction (p = 0.14). However, see the standard deviation analysis and vincentile analysis below.
coarse measure of the dispersion of an ex-Gaussian distribution that reflects both $\sigma$ and $\tau$ parameters. This analysis revealed a fully significant interaction between relatedness and sentence type on standard deviations (i.e., dispersion, $F(1, 23) = 6.07, p = 0.02$; $F(1, 22) = 11.41, p < .01$), with no significant main effects ($ps > 0.13$). Planned comparisons revealed that in the OV conditions, the dispersion was larger in the related condition ($M = 112, SD = 60$)\(^7\) than in the unrelated condition ($M = 90, SD = 27$; $t(23) = 2.44$, adj. $p < 0.05$; $t(11) = 2.73$, adj. $p < 0.05$) while in the SV conditions, the standard deviations were not different between the related condition ($M = 105, SD = 31$) and the unrelated condition ($M = 112, SD = 35$; $t(23) = 1.28$, adj.$p > 0.4$; $t(11) = 2.32$, adj.$p > 0.08$), indicating that the semantic interference effect on dispersion was only present in the OV utterances. This pattern corroborates the central tendency analysis we conducted above. This semantic effect on dispersion is visualized by means of vincentile plots in Figures 5-6.

**FIGURE 5 HERE**

**FIGURE 6 HERE**

**Discussion**

Experiment 3 showed a semantic interference effect in object-initial sentences but not in subject-initial sentences. Specifically, distractors that were semantically related to the sentence-final verb interfered with the utterance of the sentence-initial noun, but only when the sentence-initial noun was a direct object. Note that the same set of picture-distractor pairs was used as in Experiment 1, where SI effects were reliably obtained for transitive and intransitive verbs alike.

\(^7\) This larger SD value (60) was due to one participant showing an especially large standard deviation in RT. Removing this participant lowers the standard deviation to 33, but does not change the statistical results.
Therefore, we can be confident that the contrast observed in Experiment 3 is a consequence of the sentence production task, and not simply a result of poor selection of picture-distractor pairs.\(^8\) Note also that previous research tends to report more consistent semantic interference for intransitive than transitive verbs (Schnur et al., 2002; Tabossi & Collina, 2004). Therefore, it is unlikely that the observed contrast between SV and OV conditions is due to a smaller amplitude of semantic interference in the SV conditions.

The contrast between SV and OV sentences is consistent with our hypothesis that verbs are selected before the onset of objects but not before subjects, reflecting the closer dependency of objects on verbs. The contrasting pattern of SI effects casts in a new light the previous failure to find an SI effect in verb-final utterances in German (Schriefers et al., 1998). Specifically, it seems premature to draw the conclusion that a producer can dispense with verb information when processing all of a verb’s arguments in verb-final utterances. Certainly, our results do not show that speakers retrieve the verb’s syntactic information before articulating the object in every utterance. However, they do show that Schriefers et al.’s (1998) findings are, in fact, consistent with the claim that verb choices guide structural processes in sentence planning. That is, the absence of a SI effect in Schriefers et al.’s data and in the SV condition here, combined

\(^8\) A reviewer suggested that these results could reflect a potential difference in the relative ‘thematic fit’ (cf. McRae, Spivey-Knowlton, & Tanenhaus, 1998) between the target nouns and target verb (*dog-NOM howl/cat-ACC pet*) vs. target nouns and related distractor verbs (*dog-NOM cry/cat-ACC rub*). To address this concern, we conducted a post-hoc norming study (*n* = 11) where participants rated the thematic fit between the target nouns and each type of verb (e.g., *dog-NOM howl* vs. *dog-NOM cry* for SV, *cat-ACC pet* vs. *cat-ACC rub* for OV utterances) on a 7-point Likert scale, similar to McRae et al. (1998). A mixed effects analysis analogous to those used in the main experiments was conducted (this model included random intercepts for participants and items as well as random slope of Relatedness for participants and items) and revealed a marginally significant interaction between verb type (target verb vs. related distractor verb) and sentence type (SV vs. OV; \(\beta = -0.87, SE = 0.50, |t| = 1.74, p = 0.10\)) as well as significant main effects of verb type (\(\beta = 3.14, SE = 0.39, |t| = 6.02, p < 0.01\)) and sentence type (\(\beta = 1.26, SE = 0.43, |t| = 2.94, p < 0.01\)). This marginally significant interaction partially supports the reviewer’s concern. However, we find no evidence for a relationship between the magnitude of semantic interference (in Experiment 3) and thematic fit difference (between noun-target verb and noun-distractor verb) in an item based correlation analysis (*n* = 24, \(r = -0.14, p = 0.66\)). Thus, it is unlikely that the differing semantic interference effects for SV vs. OV sentences can be attributed entirely to the difference in thematic fit.
with the presence of a SI effect in the OV condition here, likely reflects the selective nature of the advance planning mechanism for verbs.

**General Discussion**

The results of the current study indicate that semantic interference (SI) from distractors related to non-initial verbs – a marker of advance verb selection – is obtained selectively before object noun articulation (Experiment 3). This selectivity is not likely to be due to the ineffectiveness of the semantic distractors for intransitive verbs (Experiment 1) or to an accidental relation between the preceding nouns and the distractors (Experiment 2). The SI effects reflected by sample means in each experiment are shown in Figure 7 below, and the same pattern was observed for the SI effect reflected by sample dispersion. These findings may reconcile the apparent conflict between the need for verb selection in order to determine the syntactic/semantic properties of pre-verbal arguments and the lack of verb-related SI effects before subject noun articulation in Schriefers et al. (1998). Based on this pattern of results, we argue that advance verb selection is selectively performed before object nouns, but not before subject nouns.

**FIGURE 7 HERE**

Before we outline the potential mechanism underlying the selective nature of advance verb planning, it is worth noting that the current result at first seems to conflict with previous findings in the scope of planning literature. In particular, the results of Experiment 3 might be regarded as in conflict with a previous finding by Meyer (1996), where the lemma of the second noun in a sentence like “the dog is next to the baby” appeared to show evidence of advance planning. That is, it appeared that object nouns, positioned after the predicate, were planned before articulation of the subject noun phrase (the dog). If a word that appears after a predicate is
already planned, this invites the conclusion that the predicate is also planned. However, this conclusion derives from the assumption that the scope of planning at the lemma level is already linear. This assumption is, as far as we know, not warranted. In fact, the production model of Bock & Levelt (1994) assumes that linearization does not occur until the positional processing stage, which is subsequent to lemma selection. Also, it is important to note that speakers repeated the same structure (either A and B or A is next to B) throughout the experimental session in Meyer (1996), potentially expanding the scope of planning. The current experiment did not allow such formulaic production. Thus, it may not be appropriate to directly compare Meyer (1996) and the current experiments.

In addition, the absence of a semantic interference effect in the SV conditions in Experiment 3 appears to be at odds with findings by Kempen & Huijibers (1983) and Schnur et al. (2002), which suggest that a verb’s lemma selection occurs even before subject noun articulation. One crucial difference between the current experiment and the previous experiments is that their target utterances had less variation in the pre-verbal noun phrases (4 variants in Kempen & Huijibers (1983), 2 variants in Schnur et al. (2002), and 24 variants in the current experiments). Also, Schnur and colleagues’ preverbal noun was a pronoun (she or he), which is particularly easy to process. Thus, although our results and Schriefers et al.’s (1998) results suggest that a verb’s lemma is not necessarily retrieved in advance of the articulation of subject nouns, it might under some circumstances be retrieved in advance of that point, in situations where there is less response variability and hence less processing difficulty in the preceding words (cf. the retrieval fluency hypothesis; Griffin, 2003).

There are at least three classes of possible mechanisms that could explain the selective pattern of advance verb planning observed in Experiment 3. The first possibility, which in a
broad sense falls under the lexicalist view of sentence production, is that encoding some structural dependency relations between verbs and their arguments requires the advance selection of verbs. One such potential dependency relation is the assignment of case to verbs’ arguments. Under this account, the selective pattern of advance verb selection we observed in Experiment 3 can be explained by a difference in how grammatical case is assigned between subject nouns and object nouns. As noted in the Introduction, accusative case is usually assigned by the lexical head V(erb), whereas nominative case is usually assigned by the inflectional head I(nflection). Thus, the necessity to assign accusative case via a verb head may require that the verb’s lemma be selected before the encoding of the object noun is completed. Alternatively, it is possible that the building of structural representations itself is dependent on verbs (e.g., Ferreira, 2000). This is a stronger lexicalist position than the first alternative, in the respect that even the most elementary structural process of building or retrieving phrase structure is considered to be dependent upon verbs under this account. In other words, the current experiments may be interpreted as evidence of partial lexical guidance in phrase structure building: structure building for the subject noun position might not be dependent on verbs, whereas structure building for the object noun position would be crucially dependent on verbs.

The second possibility, which falls under a non-lexicalist view of sentence production, in which structure building can independently occur without lexical retrieval, is that the selective advance selection of verbs observed here is due to syntactic constituency determining the scope of lemma selection. This possibility is broadly consistent with the proposal that syntactic phrases define the default scope of lemma planning (e.g., Smith & Wheeldon, 1999). This idea implies that phrase structure representations can be built prior to lemma selection (unlike the lexicalist accounts described above), and that such structural representations control the dynamics of
lemma selection processes. Although we are not aware of specific claims that the verb phrase defines the scope of planning, our data are consistent with the idea that the syntactic phrase is a determinant of the scope of planning at the lemma level. In this view, the dynamics of lemma selection are controlled by such higher-level syntactic schemes.

A final possibility is that it is the structure of semantic/conceptual representations, rather than syntactic phrases, that is the source of the contrasting pattern that we observed in the current study. Specifically, it is possible that internal arguments and verbs constitute an integrated unit that is planned together at the lemma level or higher, e.g., the message level. This is consistent with the linguistic analysis of Kratzer (1996, 2002), although it is unclear whether semantic representations in linguistic theory should be equated to message level representations in production models. Kratzer argued that external arguments should be excluded from the argument structure of predicates, and suggested instead that inflectional heads introduce external arguments. If this is the case, advance verb selection may be due to the semantic necessity to compute a predicate and its internal argument in tandem, or at least temporally closely, either at the conceptual or the lemma level.

There are of course some limitations in the current study. For instance, aside from these theoretically motivated interpretations discussed above, we acknowledge that the SV and OV utterances might differ in how much thematic processing participants must perform before starting to speak. In particular, OV utterances might require deeper thematic processing because they might have forced participants to omit the agent. However, participants in our experiment were probably not actually forced to produce OV sentences. Given the structure of the experiments, it was more natural for Japanese speakers to omit the subject than to explicitly mention the subject in the OV conditions because the agent entities in most OV pictures were
underspecified (and Japanese disfavors the use of overt pronouns) and hence hard to name without explicit instruction. This is reflected in the reaction time data: OV utterances had slightly shorter response latencies than the SV sentences, suggesting that they were, if anything, less costly than SV utterances. This difference cannot be attributed to the lexical frequency of subject vs. object nouns, as the noun-only experiment showed closely matched average latencies for S nouns and O nouns. Thus, it is unlikely that the contrastive pattern of semantic interference in SV and OV utterances can entirely be attributed to the difference in thematic processing depth.

Conclusion

The current study used an extended picture-word interference paradigm to probe the time course of verb planning, using Japanese as a test case due to its strongly verb-final word order. The results suggest that verb selection occurs selectively before articulation of the object noun, but not the subject noun in Japanese. This may reconcile past failures to find evidence for advance verb selection (Schriefers et al., 1998) with models that posit a central role for verbs in structural processes (Levelt, 1989; Kempen & Hoenkamp, 1987; Bock & Levelt, 1994; Ferreira, 2000).

---

9 One might think that, if the verb is planned in advance in the OV condition, then the reaction times in the OV sentences should generally be longer. However, it should be noted that this reaction time may largely reflect the speed of noun processing given the action picture, so it seems that naming a patient noun given a transitive action picture was easier than naming an agent noun given an intransitive picture. Also, it should be noted that verb planning might not be necessarily costly. This is because the retrieved verb lemma might facilitate the planning of object nouns via semantic priming, or what one might call the resonance between verbs and object nouns. This possible facilitative effect could counteract the cost of advance verb planning and could be additive to the semantic interference effect from the related distractors.
